Supplement of

Probabilistic end-to-end irradiance forecasting through pre-trained deep learning models using all-sky-images

S1 Forecasts with image sequences

The scenarios presented include a range of conditions, selected at random for illustration purposes:

1. Clear-sky
2. Broken cloud
3. Overcast
4. Ramp-up
5. Ramp-down

All eight models, across their four prediction horizons, are presented. We also show the corresponding ASI images for $t-n$, $t$, $t+n$, with $t$ being the current time-step and $n$ the forecasting horizon.

While we were able to filter out most of the clear-sky conditions from the data set using the method proposed by Reno and Hansen (2016), some periods still remain within the data set. This scarcity, however, did not impact the ability of the model to perform predictions in clear-sky conditions, as shown in the Fig. S1, S2, S3, and S4. The narrow probability distribution also shows that the model has high confidence while performing its prediction in these conditions.

During broken clouds, the models only show acceptable prediction patterns for the prediction horizons 5 and 10 minutes. For horizons above 10 minutes, the model behaves more or less like a persistence model. In these conditions, all models show lower confidence compared to the clear-sky conditions, as shown in Fig. S5, S6, S7, and S8.

During overcast situations, the model behaves like a persistence forecast model, but maintains a low GHI expectation with high confidence. Fig. S9, S10, S11, and S12 illustrate the forecasts and their corresponding ASI images.

In events where a cloud unveils the sun, causing a ramp-up in GHI, the models can accurately predict this ramp-up event up to a prediction horizon of 20 minutes. At a prediction horizon of 30 minutes, the model is not able to predict the ramp event. From the input image sequence, it is evident that the model likely has no information within the images suggesting such a ramp event. The probabilistic models also show much lower confidence during the ramp event, showing that the situation is evaluated correctly to determine a proper probability distributions. These effects can be observed in Fig. S13, S14, S15, and S16.

In the ramp-down scenario, the models generally predict the timing correctly, evolving to a persistence behavior the longer the horizon is chosen. As evident in the observation time-series in Fig. S17, S18, S19, and S20, there is a higher variability compared to the ramp-up scenario. The model therefore chooses to be less confident about its predictions, until it reaches clear-sky conditions later on.
